In patients with acute respiratory distress syndrome (ARDS), the risk of superimposed ventilator-induced lung injury (VILI) merits lung-protective ventilation (LPV) strategies. It has been recommended that a tidal volume \( V_t \), PEEP, and low plateau pressure \( P_{PLAT} \) are lung protective during acute respiratory distress syndrome (ARDS). This study tested the hypothesis that the aspiration of dead space (ASPIDS) together with computer simulation can help maintain gas exchange at these settings, thus promoting protection of the lungs.

**Methods.** ARDS was induced in pigs using surfactant perturbation plus an injurious ventilation strategy. One group then underwent 24 h protective ventilation, while control groups were ventilated using a conventional ventilation strategy at either high or low pressure. Pressure–volume curves \( P_{el}/V \), blood gases, and haemodynamics were studied at 0, 4, 8, 16, and 24 h after the induction of ARDS and lung histology was evaluated.

**Results.** The \( P_{el}/V \) curves showed improvements in the protective strategy group and deterioration in both control groups. In the protective group, when respiratory rate (RR) was \( \approx 60 \) bpm, better oxygenation and reduced shunt were found. Histological damage was significantly more severe in the high-pressure group. There were no differences in venous oxygen saturation and pulmonary vascular resistance between the groups.

**Conclusions.** The protective ventilation strategy of adequate \( V_t \) or \( P_{ACO_2} \), with minimal \( V_t \) and high/safe \( P_{PLAT} \) resulting in high PEEP was based on the avoidance of known lung-damaging phenomena. The approach is based upon the optimization of \( V_t \), RR, PEEP, \( I/E \), and dead space. This study does not lend itself to conclusions about the independent role of each of these features. However, dead space reduction is fundamental for achieving minimal \( V_t \) at high RR. Classical physiology is applicable at high RR. Computer simulation optimizes ventilation and limiting of dead space using ASPIDS. Inspiratory \( P_{el}/V \) curves recorded from PEEP or, even better, expiratory \( P_{el}/V \) curves allow monitoring in ARDS.

Accepted for publication: 2 April 2012
catheter from the tip of the tracheal tube and simultaneously replaced by fresh gas through the inspiratory line.\textsuperscript{16–18} With ASPIDS, dead space from the Y-piece to the trachea is completely removed without any other effect on ventilation.

In ARDS, even an experienced operator may not be able to define the optimal combination of $V_T$, PEEP, RR, and the inspiratory/expiratory ratio for reaching all physiological goals. The use of computer simulation once mathematical characterization of lung mechanics and CO\textsubscript{2} exchange has been achieved may identify beneficial combinations.\textsuperscript{19–21}

In the present study, we modelled the common clinical scenario of VILI aggravation of ARDS after the initial lung insult using surfactant perturbation followed by high $V_T$ ventilation.\textsuperscript{22,23}

The primary objective was to test the hypothesis that the GOAL strategy is more lung protective than conventional ventilation with either a low or a high plateau pressure. The endpoints were physiological parameters studied 16 h after ARDS. Both inspiratory and expiratory elastic pressure volumes were studied, plus lung histology at 24 h.

\textbf{Methods}

\textbf{Subjects and preparation}

The Local Ethics Board of Animal Research approved the study. The animals were fasted overnight with free access to water and premedicated with xylazine (2 mg kg\textsuperscript{-1}). Anaesthesia was induced by ketamine (15 mg kg\textsuperscript{-1}) and maintained with i.v. fentanyl (60 \mu g kg\textsuperscript{-1} h\textsuperscript{-1}) and midazolam (0.7 mg kg\textsuperscript{-1} h\textsuperscript{-1}). Vecuronium (0.3 mg kg\textsuperscript{-1}) provided paralysis during measurements. Sudden modifications in the heart rate and arterial pressure and increases in muscular activity were considered as indicators of distress and inadequate anaesthesia, and in this case, a bolus dose of ketamine was administered, followed by an increase in midazolam and fentanyl infusion dose.

Animals were hydrated with a priming of 1000 ml of isotonic crystalloids followed by an infusion of 125 ml h\textsuperscript{-1}. If mean arterial pressure (MAP) decreased below 40 mm Hg, dextrans was given. Blood glucose was maintained at 3.6–5.3 mmol ml\textsuperscript{-1} by administration of i.v. glucose. Body temperature was controlled at 38.5–39.5\degree C. Prophylactic i.m. streptomycin and benzylpenicillin (0.50 g and 400 000 IU, respectively) were given and the animals were prepared under sterile conditions.

A balloon-tipped, multi-lumen catheter was sited, with its tip in a pulmonary artery. Arterial and venous catheters were inserted and pressure was monitored and recorded for the right atrium and pulmonary and peripheral arteries. Arterial and central venous blood gas samples were analysed immediately for $P_{O_2}$, $P_{CO_2}$, pH, BE, Hb, and oxygen saturation (Radiometer ABL725, Copenhagen, Denmark).

\textbf{Ventilation and monitoring}

A ServoVentilator 900C (Siemens-Elema, Solna, Sweden) with a CO\textsubscript{2} Analyzer 930 for monitoring CO\textsubscript{2} elimination per minute ($V_{CO_2}$) was volume-controlled at baseline with square inspiratory flow at 20 min\textsuperscript{-1}, 15 cm H\textsubscript{2}O PEEP, and an $F_{O_2}$ of 1.0. Minute ventilation was set to maintain arterial pH at 7.30–7.45. Ventilator signals (flow rate, airway pressure, and $P_{CO_2}$) were sampled at 100 Hz.\textsuperscript{24} To minimize dead space, an active inspiratory line humidifier was used with minimal connectors to the tracheal tube.

Lung recruitment at 50 cm H\textsubscript{2}O preceded recordings of multiple elastic pressure–volume ($P_{EL}/V$) curves as described.\textsuperscript{23} The loops started with inspiration from a PEEP level of, in order: 15, 11, 7, 4, and 0 cm H\textsubscript{2}O and ended at 50 cm H\textsubscript{2}O. Higher pressures were considered to be potentially harmful. The $P_{EL}/V$ curves were modelled as a sigmoid curve.\textsuperscript{25,26} The volume was set to zero at zero PEEP during the last loop. The volume was expressed as a percentage of the initial volume at 50 cm H\textsubscript{2}O in each pig.

\textbf{ARDS model}

Lung surfactant was perturbed by inhalation of 200 breaths of 5\% dioctyl sulphosuccinate aerosol.\textsuperscript{22,23} During pressure-controlled harmful ventilation, $P_{PLAT}$ was 50 cm H\textsubscript{2}O, RR was 10 bpm, and end-expiratory pressure was $-10$ cm H\textsubscript{2}O. Dead space was added to maintain normocapnia. Harmful ventilation was continued until compliance, that is, $V_{T}/(P_{PLAT}-PEEP_{TOT})$ decreased by 25\%, or until substantial exudates appeared in the tracheal tube. ARDS was diagnosed when the $P_{ACO_2}/F_{Io_2}$ was <27 kPa after 5 min at zero PEEP with a ventilator setting otherwise as they were at baseline. If this criterion was not met, harmful ventilation continued for one or more periods of 30 min. After the diagnosis of ARDS, the animals were randomized into three groups with different ventilation strategies: a GOAL group and two control groups with conventional ventilation at high plateau pressure (HP) or conventional ventilation plus low plateau pressure (LP) (Table 1).

\textbf{Protocol}

Initially, and 0, 4, 8, 16, and 24 h after ARDS diagnosis, measurements of haemodynamics, blood gases, and $P_{EL}/V$ loops were carried out after 20 min of baseline ventilator setting at an $F_{Io_2}$ of 1.0. In the GOAL group, the goals were to reach a pH of 7.35 and a $P_{PLAT}$ of 30 cm H\textsubscript{2}O at minimal $V_{T}$. A decelerating inspiratory flow was applied with a post-inspiratory pause time of 5\%. RR should not, for technical reasons, be higher than 60 bpm. To reduce $V_{T}$, dead space down to the tip of the tracheal tube was eliminated using ASPIDS.\textsuperscript{16–18}

The principle behind the computer simulation for identifying an optimal ventilator setting has been described previously.\textsuperscript{19–21} It is based upon a physiological profile comprising a description of the elastic pressure/volume diagram, inspiratory and expiratory resistance as a function of volume, and the tidal volume of CO\textsubscript{2} eliminated in relation to $V_{T}$.\textsuperscript{21} The simulation process is based upon the target immediate physiological goals that should be achieved by ventilation. These were pH=7.35 and $P_{PLAT}$=30 cm H\textsubscript{2}O at minimal $V_{T}$.
Standard acid/base equations were used for the calculation of relationships between pH and $P_{a\text{CO}_2}$.

Ten consecutive breaths were simulated by dividing each breath into 100 steps in time, the last breath representing steady state. During each step, changes in volume and pressure were calculated from the action of the simulated ventilator and the physiological profile. The volume of CO$_2$ eliminated per minute was calculated from the single breath test for CO$_2$ describing the tidal volume of CO$_2$ related to tidal volume. The stepwise simulation process that incorporates the ASPIDS function was also previously described in detail.

The ventilator setting defined by the simulation was then implemented over 24 h, except for short periods of measurements as described. Hourly minor adjustments were carried out: PEEP to keep $P_{PLAT}$ at 30 cm H$_2$O, minute ventilation to maintain the pH at 7.35, and $F_{I\text{O}_2}$ to keep $P_{a\text{O}_2}$ within 9–12 kPa.

In the LP and HP groups, the inspiratory flow profile was square, inspiration time was 33%, and pause time was 5%. To keep $P_{a\text{O}_2}$ within 9–12 kPa, $F_{I\text{O}_2}$ and PEEP$_{TOT}$ were adjusted as shown in Table 1, following the principles of ARDSnet. According to ARDSnet, pH should be within the range 7.30–7.45 in both these groups. $P_{PLAT}$ should be within the range 25–30 cm H$_2$O for the LP group and 40–45 cm H$_2$O in the HP group. However, pilot experiments indicated that the high metabolic rates in adolescent pigs with ARDS required significantly higher $V_f$ than recommended by ARDSnet, such that in order to keep the pH at 7.30–7.45 and $P_{PLAT}$ at the target value, the combination of RR and minute ventilation had to be titrated. RR up to 35 bpm was allowed.

After 24 h, animals were killed using a bolus dose of 1.2 mg fentanyl and 100 mg ketamine, followed by fast desanguination. The lungs were removed for histological examination, and eight healthy pigs were used as controls with respect to histology. Since the primary endpoint was at 16 h after ARDS, those pigs not surviving for 16 h were replaced with others, so each group had eight animals which survived to 16 h.

**Histopathological processing**

The left lung was removed, expanded, and fixed with intrabronchial formalin. A central sagittal slice was embedded in paraffin and 5 μm thick sections were cut with a whole mount microtome, mounted on large glass slides, and stained with haematoxylin/eosin. Thirty circular areas, of 5 mm diameter, were scored according to three factors: hyaline membranes, bronchiolar neutrophil granulocyte infiltration, and bronchiolar epithelial damage. For each factor, the average areas were calculated.

**Data analysis**

**Gas exchange**

$V_{\text{D}ALV}$ and CO$_2$ elimination (VCO$_2$) were calculated from the single-breath test for CO$_2$. $Qs/Qt$ was calculated from end-capillary oxygen content (CcO$_2$), arterial oxygen content

(CaO₂) and mixed venous oxygen content (CvO₂):

\[ \begin{align*}
    Qs &= \frac{CcO₂ - CaO₂}{\dot{V}O₂} \\
    Qt &= \frac{CcO₂ - CvO₂}{\dot{V}O₂}
\end{align*} \]

\[ CcO₂ = 1.36 \times Hb \times 100 + 0.2625 \times PAO₂ \]

\[ PAO₂ = FIO₂ \times (Bp - 6.3) - \frac{Paco₂}{RQ} + FIO₂ \times Paco₂ \times (1/RQ - 1) \]

\[ CaO₂ = 1.36 \times Hb \times Sao₂ + 0.2325 \times PAO₂ \]

\[ CvO₂ = 1.36 \times Hb \times SvO₂ + 0.2325 \times PV₂ \]

**Haemodynamics**

Heart rate (HR), MAP, mean central venous pressure, mean pulmonary artery pressure (MPAP), and pulmonary capillary wedge pressure (PCWP) were measured.

Cardiac output (CO) was calculated according to Fick:

\[ CO = \frac{\dot{V}O₂}{CcO₂ - CvO₂} \]

where \( \dot{V}O₂ \) is \( O₂ \) delivery calculated as \( \dot{V}O₂ = \dot{V}CO₂/RQ \), assuming that \( RQ = 0.85 \).

Pulmonary vascular resistance (PVR) was calculated as \( (MPAP - PCWP)/CO \).

**Statistical analysis**

Data are shown as mean and standard deviation (SD). Two-way variance on ranked data was used to analyse \( P_e/V \) curves at different PEEP levels and different times. The Kruskal–Wallis test was used to detect differences between the groups in \( P_aO₂, S_vO₂, Qs/Qt, V_{D/LV}, PVR, \) and lung damage score. The Mann–Whitney test was used to further analyse the groups that differed. A P-value of <0.05 was considered significant. XLSTAT 7.5.2 (Addinsoft, New York, NY, USA) was used for analysis.

**Results**

ARDS was diagnosed after 114 (41) min of harmful ventilation. \( P_{aco₂}/FIO₂ \) was 11 (5 kPa) at zero PEEP and 47 (17 kPa) at a PEEP level of 15 cm H₂O, and was similar between the groups. Two animals which died after 2.5 h in the LP group and 10 h in the HP group were substituted. Also in the HP group, two animals died after 23 h due to arrhythmia and tension pneumothorax with hypoxia, respectively. There was no death at any time in the GOAL group. In all animals and at all times, \( P_{plat} \) and pH were within the limits given by the protocol, while \( P_{alo₂} \) was slightly higher (Table 3).

In GOAL, the settings according to computer simulation resulted in an RR of 60 bpm in most pigs, which was the maximum allowed according to the protocol. \( V_I \) in the GOAL group was less than half that seen in the LP group, while \( P_{peeptot} > 0.05 \) more than twice that in the LP and HP groups (Table 3). Also in GOAL animals, the \( I:E \) ratio was 1:1 in all but one of the animals. Intrinsic PEEP (PEEPi) was ~1 cm H₂O (Table 3).

**Mechanics of the respiratory system**

At ARDS diagnosis (0 h), the inspiratory and expiratory \( P_e/V \) curves were similar in all groups (Fig. 1). In all the groups and at all times, inspiratory \( P_e/V \) curves starting at PEEP
levels from 15 to 0 cm H2O showed a loss of volume, reflecting progressive de-recruitment for each lower PEEP level.

Families of inspiratory $P_{el}/V$ curves preceded by expirations to different PEEP levels did not completely converge, indicating that lung units collapsing at low pressures did not fully re-expand at 50 cm H2O (Fig. 1).

Inspiratory $P_{el}/V$ curves starting at zero PEEP showed, in GOAL animals, progressively higher volumes during the 24 h after ARDS, while in the LP group, and particularly in the HP group, progressively lower volumes were recorded (Fig. 2, middle panels) such that the volumes in LP pigs were higher than in HP animals ($P<0.001$).

In GOAL-treated pigs expiratory $P_{el}/V$ curves, increasing volumes were seen in the 24 h after ARDS, while decreasing volumes were seen in LP and HP animals (Fig. 2, lower panels).

At 16 and 24 h, the volumes in inspiratory and expiratory $P_{el}/V$ curves were much higher in GOAL than in LP and HP

---

**Fig 1** Inspiratory $P_{el}/V$ curves recorded from PEEP 15 to 0 cm H2O and expiratory $P_{el}/V$ curves recorded from 50 cm H2O; average in each group at 0, 16, and 24 h. Inspiratory curves showed significant differences related to starting pressure over the full pressure range apart from LP at 0 h and in HP at 24 h (two-way analysis of variance).
animals \((P<0.0001)\) (Fig. 1) and in the LP group volumes were slightly higher than in the HP group \((P<0.02)\).

**Gas exchange and haemodynamics**

At 0 h, there were no differences between the groups in terms of \(P_{aO_2}\), \(S_{vO_2}\), \(Qs/Qt\), \(V_{D/ALV}\), CO, PVR, or any other haemodynamic and gas exchange parameter. In GOAL animals at an \(F_{I O_2}\) of 1.0, \(P_{aO_2}\) was higher than in LP animals from 4 h onwards, and in HP animals from 8 h. After 4 h, \(P_{aO_2}\) was not different from the pre-ARDS values in the GOAL animals (Fig. 3). Throughout the study period, CO and \(S_{vO_2}\) did not differ between the groups. Accordingly, \(P_{aO_2}\) inversely reflected variations in \(Qs/Qt\).

**Histopathology**

In untreated healthy pigs, the lung injury score was close to 0. At 24 h, scores were higher than in healthy pigs in all the groups \((P<0.001)\) and differed between the groups \((\text{ANOVA, } P=0.033)\) (Fig. 4).
Fig 3 Haemodynamics and gas exchange during the study. GOAL differed from the LP and HP as indicated by asterisks in blue and green colours, respectively. Data are expressed as mean and SD.
Discussion

In an ARDS pig model, induced by VILI after surfactant perturbation, the GOAL strategy based upon proper pH, safe $P_{\text{PLAT}}$, and minimal $V_T$, together implying high PEEP$_{\text{TOT}}$, resulted in improvement over 24 h after initiation of ARDS. Accordingly, the GOAL strategy was shown to be lung protective relative to an alternative strategy with the same $P_{\text{PLAT}}$ in which deterioration was observed.

The tools used were goal-orientated ventilation facilitated by computer simulation, dead space reduction by ASPIDS, and for monitoring, advanced $P_{\text{aw}}/V$ recording. On the basis of the characterization of the physiological status of the animal with respect to mechanics and CO$_2$ exchange, the setting of several ventilator parameters, which together were expected to minimize lung injury, was defined. This approach is motivated by the judgement that there is no ‘best PEEP’ without taking into account $V_T$ and no ideal $V_T$ without regarding $P_{\text{PLAT}}$, etc. Trying to identify the role of specific steps of ventilator setting may, in this respect, be futile. The GOAL strategy obviates the need for titration of the ‘best PEEP’.

In GOAL, a $P_{\text{PLAT}}$ of 30 cm H$_2$O and an arterial pH of 7.35 were chosen according to ARDSnet. We refrained from practising permissive hypercapnia to further reduce $V_T$, as this remains a controversial issue. A decelerating flow was accomplished by computer control of ventilator function. The reason for using the decelerating flow was to improve CO$_2$ exchange by prolonging the mean distribution time. In the light of recent findings, a constant flow, a short inspiratory time, and a post-inspiratory pause time of more 5% would have been chosen as this has been found to further enhance CO$_2$ exchange at constant $V_T$. It was considered that minimal $V_T$ is a central issue in LPV. Recently, Bruhn and colleagues confirmed, by dynamic CT, that cyclic collapse and opening is reduced by lower $V_T$, providing direct evidence that low $V_T$ ventilation may be lung protective by reducing this phenomenon. Very recently, it has also been experimentally proven that an open lung strategy, aimed at reducing dynamic strain, improves arterial oxygenation, but fails to positively affect respiratory mechanics and pulmonary inflammation compared with mechanical ventilation with lower PEEP according to ARDSnet.

A high dead space pre-empts isocapnic ventilation at a very low $V_T$. An active humidifier and minimal connectors between the y-piece and the tracheal tube were used in all the groups in our study. In GOAL, ASPIDS was applied for optimal dead space reduction. The ventilator setting defined with computer simulation resulted in $V_T\approx 5.8$ ml kg$^{-1}$, RR$\approx 58$ min$^{-1}$, and $I:E$ ratio$\approx 1:1$. That $V_T$ could not be further reduced reflects the high CO$_2$ production in these adolescent pigs and very high physiological dead space in the ARDS model. The high $I:E$ ratio reflects that computer simulation recognized that a short mean distribution time would not otherwise allow efficient CO$_2$ exchange. As stated, recent findings would have encouraged the use of a longer pause time.

In GOAL, an open lung strategy comprised an initial recruitment manoeuvre followed by a high-PEEP and low-$V_T$ ventilation. The recruitment manoeuvre to 45–50 cm H$_2$O may have left some units collapsed which might be recruited at a higher, potentially injurious pressure. A recruitment manoeuvre has a transient effect, while a high PEEP.

Fig 4 Lung injury score in individual pigs at the end of the study.
combined with a low $V_t$ maintains recruitment and enhances arterial oxygenation.\textsuperscript{34 35} Hence, the strategy was based on moderate recruitment, low $V_t$, and high PEEP.

In an open lung, oxygenation can be achieved at reduced ventilation just by increasing $F_{\text{IO}_2}$.\textsuperscript{16} However, CO\textsubscript{2} exchange depends strictly upon alveolar ventilation. At high $V_t$, shear forces in lung zones undergoing repeated collapse and re-expansion (RECOREX) lead to VILI.\textsuperscript{37 – 39} Closing pressures are much lower than opening pressures, but their distributions overlap.\textsuperscript{17 40 41} At a safe $P_{\text{PLAT}}$, it appears impossible to maintain complete aeration. Even at a PEEP of 20 cm H\textsubscript{2}O, some units will close. Reasonably, these units also have particularly high opening pressures. If $V_t$ is so low that the difference between PEEP and $P_{\text{PLAT}}$ is less than the difference between closing and opening pressures, these units remain closed during breaths. Accordingly, both volutrauma related to RECOREX and barotrauma due to high $P_{\text{PLAT}}$ may be abolished at very low $V_t$ and high PEEP. This contention is underpinned in Figure 5, in which distributions of opening and closing pressures refer to the study by Crotti and colleagues\textsuperscript{40} and which are in line with patterns of inspiratory and expiratory $P_{el/V}$ curves in the present study.

The conclusion is that it is rational to reduce $V_t$ to the lowest possible level.

For each lower level of PEEP, families of inspiratory $P_{el/V}$ curves showed, consistently in each animal, a loss of volume, confirming wide distributions of closing pressure in ARDS below a PEEP of 15 cm H\textsubscript{2}O. During insufflations, the $P_{el/V}$ curves started in each animal to approach one another at pressures above $\sim$20 cm H\textsubscript{2}O, but the volume losses were incompletely regained during insufflation up to PEEP of 40–50 cm H\textsubscript{2}O. The findings indicate a wide range of opening pressures that are higher than closing pressures. The estimated opening and closing pressures agreed with previous observations.\textsuperscript{17 40 41} In this respect, the ARDS pig model is similar to that seen in ARDS in patients.

An RR as high as 60 bpm overlaps with high-frequency ventilation. Simulation was based upon classical models of mechanics and CO\textsubscript{2} exchange plus the concept of mean distribution time.\textsuperscript{28 – 31} The settings defined by computer simulation led to predefined goals, implying that classical physiology is valid in ARDS up to at least 60 bpm.\textsuperscript{21} In spite of short expirations at high RR and high $I:E$ ratio, $P_{\text{PEEP}_{TOT}}$ was close to the set PEEP.

In GOAL, $P_{\text{A}_{\text{IO}}}$ became normal as early as 4 h. The $P_{el/V}$ curves showed a continuous improvement until 24 h (Fig. 2). In the LP and HP groups, inspiratory $P_{el/V}$ curves recorded at a PEEP of 15 cm H\textsubscript{2}O, and expiratory $P_{el/V}$ curves showed a clear continuous deterioration. These types of curves starting when the lungs are reasonably well aerated reveal mainly elastic properties. In contrast, the inspiratory $P_{el/V}$ curves recorded from zero PEEP are influenced by continuous inspiratory re-opening.\textsuperscript{26 42 43} In ARDS, they are not useful in monitoring elastic properties.

In the LP group, $P_{\text{PPLAT}}$ was similar to that in GOAL, while $V_t$ was twice as high. The non-favourable evolution in LP is therefore explained by volutrauma rather than barotrauma. Much lower PEEP in LP than in GOAL favours RECOREX, leading to lung injury. Results in HP and LP were, in general, similar. The histology suggested more pronounced changes in HP in spite of much higher $V_t$ and $P_{\text{PPLAT}}$. Similar findings in LP and HP suggest that in both the groups, injurious effects of ventilation were high enough to maintain a vicious circle in which shear forces caused by RECOREX led to lung damage, leakage of plasma proteins, and increasing surfactant inactivation, thereby accentuating lung collapse and VILI.\textsuperscript{22}

Like in ARDSnet, $P_{\text{PPLAT}}$ in LP should not exceed 30 cm H\textsubscript{2}O and the pH should be about 7.35.\textsuperscript{9} In LP, $V_t$ was much higher compared with the 6 ml kg\textsuperscript{-1} body weight recommended by ARDSnet. A limitation of our study is that we did not achieve titration to a low enough $V_t$ to mitigate lung injury. The GOAL strategy is to find a truly minimal $V_t$. When, from the end-inspiratory situation, a minimal $V_t$ is expired, the end-expiratory elastic recoil pressure, that is, $P_{\text{PEEP}_{TOT}}$, will be the highest one compatible with the selected $P_{\text{PPLAT}}$ and minimal $V_t$. This will keep the lung open, so as to minimize the required $F_{\text{IO}_2}$ and reduce oxytrauma. In this study, even in the GOAL group, $P_{\text{PEEP}_{TOT}}$ was quite low in spite of the short

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Fig5.png}
\caption{Realistic distributions of opening and closing pressures of lung units in ARDS. Arrows illustrate the range $P_{\text{PEEP}_{TOT}}$ to $P_{\text{PPLAT}}$ under different ventilation regimes. Arrow 1 refers to obsolete high $V_t$/flow PEEP ventilation at which most lung units undergo RECOREX, while high $P_{\text{PPLAT}}$ causes barotrauma. Arrow 2 represents moderate $V_t$/high PEEP ventilation. Only units with high closing pressure undergo RECOREX, but barotrauma remains important. Arrow 3 illustrates moderate $V_t$/flow PEEP$_{TOT}$. Low $P_{\text{PPLAT}}$ prevents barotrauma, but many lung units collapsing during expiration undergo RECOREX. Arrow 4 illustrates very low $V_t$/high PEEP ventilation. Low $P_{\text{PPLAT}}$ prevents barotrauma. Only those units with particularly high closing pressures represented by the pink area will close. If these units also have high opening pressures (pink area), they will remain collapsed throughout the breath so as to fully prevent RECOREX.}
\end{figure}
expiration at a high I:E ratio and a high RR. If PEEP is not generally available, the basic principle to use the lowest feasible VT at high but safe Pplat to keep the lung open may be applied in clinical studies. Dead space should be minimized by not using humidifying filters or connectors with unnecessarily high volumes. Reduced dead space paves the way for higher RR than conventional RR. At a higher RR, VT may be lowered much more than the primary dead space reduction itself. At high RR, an I:E ratio of up to 1:1 should be applied in order to improve alveolar equilibration of CO₂ by diffusion. Lessons learned may be applied in different clinical settings. It is possible that improved mechanical ventilation may lessen the need for extreme rescue therapies such as extra-corporeal gas exchange in viral pneumonia. More commonly, improved mechanical ventilation during anaesthesia may mitigate perioperative lung injury.44

Conclusions

A valid strategy for LPV in ARDS is to define the immediate physiological goals, which may be adequate pH or PaCO₂, safe Pplat, and minimal VT. With these, high PEEP will keep the lung open and reduce the required Fio₂. Dead space reduction is fundamental for RR in ARDS. Classical physiology is applicable at rates overlapping high-frequency ventilation. Computer simulation may guide ventilator settings so as to optimize goal-orientated ventilation. Inspiratory elastic pressure–volume curves recorded from high PEEP or even better, expiratory curves, allow the monitoring of improvements and deteriorations in ARDS.

Acknowledgements

We thank Ingegerd Göransson, Elisabet Åström, and Berit Olsson for their extensive assistance throughout the study, in particular their skilful experimental work and data acquisition; Lisbet Niklason, Björn Drefeldt, and Gerth-Inge Jönsson for help with software and hardware; Sten Blomquist and Edgar Grins for valuable assistance during animal preparation; Peter Dahm and Lena Åkesson for help with equipment; and Anders Larsson and Thomas Dyhr for valuable advice.

Declaration of interest

None declared.

Funding

The study was funded by the Swedish Heart Lung Foundation, the Medical Faculty of Lund University, and Region Skåne.
